Abstract

Some recent publications on ferromagnetic resonance in amorphous wires mention presumably new kind of anisotropy, called there *circumferential anisotropy*, as an explanation of various observed spectral features. In this paper we argue that there is no special reason to speak of the new kind of anisotropy, since the observed spectra can be well described in terms of more traditional uniaxial and surface anisotropies alone.

Key words: Amorphous systems – wires, Anisotropy – theory, Anisotropy – surface, Ferromagnetic resonance, Coatings

Our earlier investigations [1] of FMR in magnetic, amorphous, glass-coated microwires (diameter $\sim 15 \mu\text{m}$, few mm long) have shown, that no satisfactory description of the observed resonance lines could be achieved with the usual form of the uniaxial anisotropy energy, given by $E = K_u \sin^2 \theta$, even if appended with an extra term $K_4 \sin^4 \theta$.

The ferromagnetic wires are amorphous bodies, with no long range chemical ordering, yet they cannot be considered as magnetically isotropic objects. Very high cooling rate ($\sim 10^6$ K/s) during manufacturing process, together with the presence of a glassy, non-magnetic outer shell are good reasons for considering the wire as consisting of two essential parts: inner, cylindrically shaped inner core

and the outer coaxial tubular shell. The interface between the two is probably not very well defined, however it is obvious, that such a system cannot be treated in the same manner as uniform, classical, free-standing ‘infinitely long cylinder’. In this paper we will try nevertheless to apply the classical theory of ferromagnetic resonance in isotropic ellipsoids, assuming that the wire is magnetized uniformly.

The spectra simulations [1], covering very broad ranges of the searched anisotropy constants, up to $\pm 10^7$ erg/cm³, were carried out using methods of interval arithmetic [2], which is extremely reliable and accurate technique. Neither the number of observed resonances, nor their positions could be reproduced satisfactorily when only two uniaxial anisotropy terms, K_u and K_4 , were taken into account. Being unsure what could be the nature of the so called *helical* and *circumferential*

anisotropies [3], we decided to study the possible effects of the surface anisotropy on the resonance properties of cylindrically-shaped samples. The assumption that the surface anisotropy is of simple uniaxial type (easy or hard axis normal to the wires' surface) leads to the contribution to the free energy in the form $E \sim K_s \sin^2 \theta$, indistinguishable experimentally from the one describing the inner core. The uncontrolled stresses, present at the wire-glass interface, and acting via inverse magnetostrictive effect, due to symmetry reasons cannot be held responsible for the orientation of easy/hard direction other than along the wire.

Consider now two identical spins, treated here as classical vectors, located at the circumference of a circle with radius ρ , and separated by the distance δ one from another, both tangent to the circle and lying in its plane. The Heisenberg exchange energy of their interaction is $E = -2J(\mathbf{S}_1 \cdot \mathbf{S}_2)$, with J denoting the exchange integral. This energy may be expressed as well as the function of the angle between both spins: $E = -2JS^2 \cos \phi_{12}$, where $S = |\mathbf{S}_1| = |\mathbf{S}_2|$. Given the spacing δ and $\phi_{12} \approx \delta/\rho \approx \sin \phi_{12}$, we can approximate

$$\cos \phi_{12} = \sqrt{1 - \sin^2 \phi_{12}} \approx 1 - \frac{1}{2} \left(\frac{\delta}{\rho} \right)^2 \quad (1)$$

Therefore the difference of energies of this system when both spins are lying on a straight line ($E_1, \phi_{12} = 0$) or are located on the circle ($E_2, \phi_{12} \neq 0$) is equal to $|E_2 - E_1| = |J|S^2 \left(\frac{\delta}{\rho} \right)^2$, i.e. it is inversely proportional to the squared radius of the circle. Exactly the same result would be obtained, if the spins were oriented along the radii of the circle. We can identify this difference in energy as arising entirely from the fact, that the surface, where the spins are located, is curved. In other words, the non-vanishing surface anisotropy energy density is a geometric effect, proportional to the squared local curvature of the magnetized surface and to the strength of *isotropic* exchange interactions. Perhaps this effect should be called *exchange anisotropy*, since its origin is similar to the one first described in [4], with magnitude as high as 7×10^6 erg/cm³ for 200 Å fine Co particles.

In order to calculate the surface contribution to the total anisotropy one has to integrate proper

expression along the elliptical path, with continuously varying curvature, being the edge of the wires' cross-section by the plane parallel to its magnetization vector. Doing so we obtain $E_s \propto |\cos \theta|$, therefore the anisotropic part of the free energy density should read

$$E = K_u \sin^2 \theta + K_4 \sin^4 \theta + K_s |\cos \theta| \quad (2)$$

where K_u is an ordinary uniaxial anisotropy term, modified by the presence of the surface, K_4 is higher order uniaxial anisotropy term, and K_s is related to the following factors: intrinsic surface anisotropy, the sample diameter and isotropic exchange interactions.

The unusual form (2) of the free energy density derived in this paper, suggests that the FMR spectrum of a thin, glass coated, amorphous wire can substantially differ from the one observed in massive, free-standing samples. In particular, there may be more than just one resonance line for any given orientation of the external magnetic field. Additionally, the lack of smoothness of the anisotropy energy at $\theta = \frac{\pi}{2}$ should be the reason for unusual shape of the resonance absorption. The peak, if any, observed in rather strong external field, oriented nearly perpendicularly to the wire, cannot be adequately described by the standard formalism of small vibrations. The free precession of a magnetization vector around its equilibrium position will be, in this case, strongly disturbed (damped) twice per every revolution. This should lead to substantial increase of the peak's linewidth. Also, if the external field is not exactly perpendicular to the wire, then the resonance peak should be clearly asymmetric. The overall shape of the resonance line should be sensitive to the magnitude of the exciting field, i.e. to the applied microwave power level. All those effects were indeed observed experimentally [1].
